"Grid-point storms"

• If convective heating/mixing (stabilisation) is not adequately represented in the model, the model might get saturated under moist and/or strong forcing conditions – it then develops an explicit turnover to get rid of the instability. However, these resolved-scale updrafts are not at the right scale in models with grids larger than say 5-10 km (actual convective updraft radius are generally smaller than 1-2 km).

• These unphysical strong ascents (mass fluxes) in the model produce excessive "stratiform" rain, too deep lower tropospheric pressure systems and strong divergence at upper levels, destroying the actual Jet structure - these model errors then propagate and grow quickly, affecting heavily the forecast skill of the model.

"Grid-point storms" as a historical problem

CAPE climatology

This problem is particularly important over regions with high convective instability (CAPE), i.e.¹³⁵ over North America (Great Plaines) during Northern Hemispheric Spring, South America (Southern hemispheric spring), but also over the tropical Pacific Ocean (Indonesia region).

Shown is the monthly mean distribution of CAPE for May at 00 UTC over N America- Nota: typical values for Europe for this period are just about half

"Grid-point storm": History 2002/2003

48h forecasted convective and stratiform rainfall with different versions of convection scheme/trigger

Note the large amount of stratiform rainfall in CY25R1 (2002) over central Great Plaines that is replaced by a smooth distribution of convective rainfall in new cycle (upper left picture)

Tropical Forecast Biases and Physics

Forecasts of tropical atmosphere are naturally very sensitive to any changes in the convection scheme

• On the longer term (10-20 days) the tropical atmosphere is in radiative convective equilibrium, so that the detrainment of water substance by the convection significantly affects the upper-tropospheric temperature and moisture biases

• The upper-tropospheric wind biases are also strongly affected by the entrainment coefficient in the momentum flux formulation - "cumulus friction" and organized mass detrainment

• The convergence/precipitation in the ITCZ and Headly/Walker circulations strongly affected by the deep convection, but equivalent important is the representation of shallow convection in the subtropics determining the moist low-level flow in the Tropics

• Furthermore, statistics on tropical variability (cyclones and Madden-Julian oscillation) are also strongly affected by the convection parameterization

Wind Gusts in the IFS

Gusts are computed by adding a turbulence component and a convective component to the mean wind:

$$U_{gust} = U_{10} + 7.71U_* f(z/L) + \underbrace{0.6 \max(0, U_{850} - U_{925})}_{deep \ convection}$$

where U_{10} is the 10m wind speed (obtained as wind speed at first model level, or interpolated down from 75m level), U_* is the friction velocity - itself obtained from the wind speed at the first model level, and L is a stability parameter.

The convective contribution is computed using the wind shear between model levels corresponding to 850 hPa and 950hpa, respectively.

Wind Gusts ('turbulent' & 'convective gusts')

Wind Gusts ('turbulent' & 'convective gusts)

ECMWF 16 km

AROME 2.5 km

The lower resolution model can easily miss local convective events -though the 2.5 km still tends to overestimate their intensity

NWP Training Course Convection IV: Forecasting and diagnostics

Forecasting and discussion of weather maps

The prediction of (convective) rainfall by the model is not always perfect, but ! The large-scale situation is generally well-forecasted by the model. Therefore, a good forecaster should be able to predict regions of convective activity from the large-scale fields

..... it will be shown that with the present forecast system (10-30 km resolution) strongly forced mesoscale convection with trailing stratiform area can be reasonably well predicted typically a few days in advance

Reminder: Midlatitude Convection

Forcing of ageostrophic circulations/convection in the right entrance and left exit side of upper-level Jet

Acceleration/deceleration of Jet

Thermally direct circulation

NWP Training Course Convection IV: Forecasting and diagnostics Slid

Reminder: Troughs or PV anomalies

"horizontal" cross section of Geopotential on constant pressure surface or PV on constant potential temperature surface

•It is equivalent to look at Troughs at constant pressure surface or to look at PV at constant potential temperature surfaces

•To know what is going on in the atmosphere it is sufficient to look at the low-level perturbation (flow) and at the upper-level flow (perturbation)

•If we look at PV instead of Geopotential we will see more structure (for reasons not explaine here)

Reminder: PV thinking the atmosphere below and above a PV anomaly (vertical cross section)

There is a cyclonic vortex around the upper-level PV anomaly (the tropopause is marked by the pink line). The atmosphere below the anomaly is relatively cold and less stable
